ABSTRACT

We present a multi-instrument chemical analysis of the stars in the metal-poor S2 halo stream using both high- and low-resolution spectroscopy, complemented with a re-analysis of the archival data to give a total sample of 62 S2 members. Our high-resolution program provides α -elements (C, Mg, Si, Ca and Ti), iron-peak elements (V, Cr, Mn, Fe, Ni), n-process elements (Sr, Ba) and other elements such as Li, Na, Al, and Sc for a subsample of S2 objects. We report coherent abundance patterns over a large metallicity spread (~ 1 dex) confirming that the S2 stream was produced by a disrupted dwarf galaxy. The S2's α -elements display a mildly decreasing trend with increasing metallicity which can be interpreted as a “knee” at $[\text{Fe}/\text{H}] < -2$. However, even at the high end of $[\text{Fe}/\text{H}]$, S2's $[\alpha/\text{Fe}]$ ratios do not climb down from the halo plateau, signaling prehistoric enrichment pattern with minimal SN Ia contribution. At the low metallicity end, the n-capture elements in S2 are dominated by r-process production: several stars are Ba-enhanced but unusually extremely poor in Sr. Moreover, some of the low- $[\text{Fe}/\text{H}]$ stars appear to be carbon-enhanced. We interpret the observed abundance patterns with the help of chemical evolution models that demonstrate the need for modest star-formation efficiency and low wind efficiency confirming that the progenitor of S2 was a primitive dwarf galaxy.

Key words: stars: abundances – Galaxy: evolution – Galaxy: formation – Galaxy: Halo – Galaxy: Kinematics and Dynamics

[★] Based on observations made with the ESO Very Large Telescope at the La Silla Paranal Observatory; with Gran Telescopio

de Canarias at the Observatorio Roque de los Muchachos– Isla

1 INTRODUCTION

In the current cosmological structure formation theory, dwarf galaxies are not the main building blocks of bigger systems, although they do represent a good fraction of the bricks or mortar from which the *stellar halos of galaxies* like our own are constructed (e.g. Johnston et al. 1996; Helmi & White 1999; Bullock & Johnston 2005; Bell et al. 2008; Cooper et al. 2010; Font et al. 2011; Belokurov 2013; Deason et al. 2016). It was therefore to great surprise that upon a careful inspection, the chemical abundance patterns of the surviving high-luminosity (so called Classical) dwarfs did not match that of the Galactic stellar halo (see Shetrone et al. 2001, 2003; Venn et al. 2004; Helmi et al. 2006; Kirby et al. 2009; Tolstoy et al. 2009). The arrival of the ultra-faint dwarfs (UFDs) provided a glimmer of hope as they appeared to contain significantly more metal-poor stars compared to their more luminous counterparts (see e.g. Kirby et al. 2008; Simon et al. 2010; Koposov et al. 2015; Walker et al. 2016). While at low $[\text{Fe}/\text{H}]$ a much better match is indeed observed between the UFDs and the stellar halo in terms of the α -elements and carbon (see e.g. Feltzing et al. 2009; Frebel et al. 2010b; Norris et al. 2010c; Gilmore et al. 2013; Salvadori et al. 2015; Spite et al. 2018; Yoon et al. 2018), the neutron-capture abundances are clearly out of kilter: the bulk of the UFDs are under-enhanced in Ba and Sr compared to the halo, yet there are also surprising examples of extreme over-abundance (see e.g. Koch et al. 2008b, 2013; Roederer & Kirby 2014; Ji et al. 2016c; Roederer et al. 2016; Hansen et al. 2017; Ji et al. 2019).

Naturally, the question of figuring out the physical conditions at the epoch of formation for the stars in the halo is best addressed by studying the actual progenitors, i.e. those unfortunate satellites that not only were accreted by the Milky Way but were also taken apart by the Galactic tides at some distant past. As they have breathed their last, presently these galaxies can only be scrutinized by identifying their debris scattered around the Galactic halo, piecing these shreds together and applying numerical models to their re-assembled cadavers. Even though this is in fact the main tenet of the popular sub-field of Astrophysics known as Galactic Archaeology, not many such forensic studies are currently on record. Large numbers of detailed chemical abundances have so far only been collected and analysed for two stellar halo structures: the Sagittarius stream (see Monaco et al. 2007; Chou et al. 2007; de Boer et al. 2015; Carlin et al. 2018; Hayes et al. 2020) and the *Gaia* Sausage (see Nissen & Schuster 2010; Helmi et al. 2018; Mackereth et al. 2019; Vincenzo et al. 2019; Molaro et al. 2020; Feuillet et al. 2020). Additionally, a small number of stars in globular cluster streams have been under the magnifying glass of high-resolution spectroscopy (e.g. Roederer & Gnedin 2019).

This, as one might guess, is not for the lack of trying. In the dark, pre-*Gaia* ages, many a campaign to follow up lower-mass stellar streams spectroscopically started with high hopes but ended in anger and disappointment.

Some success has been reported for the highest surface brightness stream – that emanating from a number of Milky Way globular clusters (e.g., Odenkirchen et al. 2009; Kuzma et al. 2015; Ishigaki et al. 2016; Belokurov et al. 2006; Sollima et al. 2011; Myeong et al. 2017b), yet fluffier sub-structures were not easy to tame (Casey et al. 2013, 2014; Navarrete et al. 2015). The key to success turned out to be astrometry, as was beautifully demonstrated in the pioneering work of Helmi et al. (1999) who used Hipparcos (Perryman et al. 1997) proper motions complemented with ground-based measurements to identify a clump of stars with peculiar angular momenta passing not far from the Sun. Out of 12 possible members, 3 stars had positive vertical velocity while 9 had negative vertical velocity. Helmi (2008) later provided a simulation that suggested an interpretation of the data as the partially phase-mixed debris of a heavily disrupted satellite. The two separate velocity groups could be on different wraps of the now destroyed satellite, one moving downward, one upward, with respect to the Galactic plane. The fact that this small stellar clump stood out from the bulk of the Galaxy due to its high velocity allowed a significantly more robust membership identification (see e.g. Chiba & Beers 2000; Re Fiorentin et al. 2005; Kepley et al. 2007). Building upon these analyses and further refining the kinematic selection of the stream members, Roederer et al. (2010) carried out a high-resolution spectroscopic follow-up campaign of the stars in the halo structure identified by Helmi et al. (1999). Theirs is the first and only example of a detailed chemical reconstruction of a low-mass disrupted sub-system.

The arrival of the unprecedented high-quality astrometry from the *Gaia* space observatory (Gaia Collaboration et al. 2016) has completely changed the game of searching for the halo sub-structure. The last three years have witnessed an avalanche of discoveries of disrupted Galactic satellites in the Solar vicinity (Helmi et al. 2017; Myeong et al. 2017a; Belokurov et al. 2018; Myeong et al. 2018c,a,b; Koppelman et al. 2018; Myeong et al. 2019; Borsato et al. 2020; O’Hare et al. 2020; Yuan et al. 2020) and further out from the Sun (Ibata et al. 2018; Malhan et al. 2018; Koposov et al. 2019; Ibata et al. 2019b,a; Grillmair 2019). The more distant streams are powerful probes of the Galactic gravitational potential (Koposov et al. 2010; Gibbons et al. 2014; Bowden et al. 2015; Bovy et al. 2016; Bonaca & Hogg 2018; Erkal et al. 2019; Malhan & Ibata 2019). The nearby sub-structures, on the other hand, present a unique opportunity to understand the physics governing structure formation in the high-redshift Universe via the chemical analysis of their (bright and high surface gravity) member stars. An abundance study of the distant halo stars is of course possible (see e.g. Battaglia et al. 2017) but is always limited to giant stars at fainter apparent magnitudes thus making such an endeavour much more laborious.

One of the first thorough sweep through the local stellar halo with *Gaia* data was performed by Myeong et al. (2018c,a) who used proper motions obtained from the combination of the *Gaia* DR1 positions and the recalibrated Sloan Digital Sky Survey (SDSS) astrometry (Deason et al. 2017; de Boer et al. 2018) further augmented with the SDSS spectroscopy. They relied on Main Sequence stars for which a well-tested photometric parallax relation had been estab-

de La Palma; and with the Hobby-Eberly Telescope at McDonald Observatory.

† E-mail: daguado@ast.cam.ac.uk

lished (Ivezić et al. 2008; Williams et al. 2017). The second most significant substructure detected with 73 likely members in the velocity space from this SDSS-*Gaia* dataset (Myeong et al. 2018a) was a cold and metal-poor stellar stream on a nearly polar orbit, plunging through the Galactic disc. The stellar stream was dubbed S2 as the connection between the stream and the stellar substructure detected by Helmi et al. (1999) was not immediately apparent as the local volumes covered in two studies were different. On closer examination, the S2 members picked up by Myeong et al. (2018a) can be associated with the negative v_z portion of the group originally described by Helmi (2008). As the SDSS-*Gaia* provides more extended volume coverage of the local halo, Myeong et al. (2018a) could reveal that the substructure has a clear stellar stream morphology extended along the direction of its streaming motion, supporting the interpretation of an additional wrap of a stream. They modelled S2 using a library of tidal debris produced by Amorisco (2017), and argued that its progenitor had a total mass of $\sim 10^9 M_\odot$ and a stellar mass of $\sim 10^6 M_\odot$. In a follow-up study, Myeong et al. (2018b) searched for stellar overdensities in the space of orbital actions, and the S2 stream was once again recovered at high confidence. This time, a group of stars with positive vertical v_z motion (with comparable action variables) were also included as potential members in addition to the prominent negative v_z clump. However, the positive v_z portion appears more diffuse and ambiguous.

The bulk of the high-confidence S2 members in the Myeong et al. (2018a) sample is within 1-3 kpc from the Sun, the closest to us ultra-faint dwarf is at a distance of ~ 20 kpc (Belokurov et al. 2007; Laevens et al. 2015), while the closest satellite similar to S2's progenitor in mass is beyond 50 kpc. In the spectroscopic studies of dwarf galaxies, gaining a factor of 10-30 in distance can be revolutionizing. This implies that very bright stars can be measured and therefore even faint traces of elements can be detected. Moreover, unlike in the distant halo, in the nearby tidal stream, unevolved stars with higher surface brightness are available for follow-up at comfortable apparent magnitudes. Dwarf star spectroscopy circumvents or mitigates the need to correct for processes that lead to creation, destruction and diffusion of elements in the stellar interior, just under the atmosphere (e.g. Spite & Spite 1982a; Thoul et al. 1994; Busso et al. 1999; Lind et al. 2008; Karakas 2010; Michaud et al. 2015; Paxton et al. 2018).

Here we report the results of a new spectroscopic campaign to reconstruct the chemical fingerprint of the progenitor of the S2 stream. We take advantage of the astrometry available as part of the *Gaia* Data Release 2 (GDR2, Gaia Collaboration et al. 2018) to revise the stream membership. Our gold-plated S2 candidate members have been followed up with high-resolution spectroscopy on 8 and 10-m class telescopes. We expand the S2's chemical anthology by adding abundances from low-resolution spectra, both new, obtained by us as well as the archival data from SEGUE, BOSS, APOGEE and LAMOST re-analysed to provide a consolidated view of the stream. Additionally, we revisit the dataset obtained by Roederer et al. (2010) and re-classify their candidate stream members using the GDR2. As a result our S2 chemical library covers a wide range of metallicity and contains accurate abundances of carbon; α -elements

Mg, Ca, Si, Ti; iron-peak elements V, Cr, Mn, Co and Ni; as well as n-capture elements Sr and Ba.

The Paper is organised as follows: in Section 2, a summary of the S2 stream and the target selection for the spectroscopic follow-up are described. In Section 3, observations and data reduction are explained. In Section 4 we present the two-step analysis of our S2 catalogue, while a detailed discussion of the results is presented in Section 5 together with the comparison with chemical evolution models. Finally, Section 6 presents the summary and conclusions.

2 TARGET SELECTION

2.1 High Quality Sample of S2 Members

The identification of S2 candidate stars in Myeong et al. (2018a,b) was made from the SDSS-*Gaia* catalogue, which is a crossmatch between *Gaia* Data Release (DR) 1 (Gaia Collaboration et al. 2016), SDSS DR9 (Ahn et al. 2012) and LAMOST DR3 (Luo et al. 2015). This catalogue of Milky Way Halo stars consists of 61 911 MSTO and 222 BHB stars with full six-dimensional phase space information and basic stellar parameters (see Section 2.1 of Myeong et al. 2018b, for more details). As *Gaia* DR2 was not available at that time, the detection made use of proper motions obtained from *Gaia* DR1 and SDSS astrometry (see Deason et al. 2017; de Boer et al. 2018). These stars were re-analysed with later released *Gaia* DR2 proper motions, and 52 stars were reconfirmed as high quality members based on their revised action variables (O'Hare et al. 2020).

The projected view of the stream in the Galactic coordinates (X, Y, Z) is shown in Fig. 1. Here, (X, Y) are coordinates in the Galactic plane with X pointing away from the Galactic Centre and Y in the direction of Galactic rotation, whilst Z is perpendicular to the Galactic disc. The majority of the S2 stars form a clear stellar substructure passing through the Galactic disc, just outside of the Solar circle. The velocity vectors of the stars are well aligned with the direction of the stellar stream. The median Galactocentric coordinates of the stream are (X, Y, Z) = (8.7, 0.5, 0.7) kpc, with median actions of (J_r, J_ϕ, J_z) = (223, 1394, 1141) $\text{kms}^{-1}\text{kpc}$, median orbital eccentricity, $e = 0.34$, and median orbital inclination, $i = 58.0$ deg.

The main portion of S2 (with negative v_z motion) appears very prominently in the velocity space (see e.g., Fig. 4 of Myeong et al. 2018a). Its distribution is well separated from the main bulk of the field halo stars. Their spatial distribution in the local halo is also very prominent as a stellar stream which also well coincides with the direction of the streaming motion. For our high resolution spectroscopic follow-up described in Section 3, we chose targets (marked as stars in Fig. 1) that are well located in the stream to further minimise the potential contamination.

While the majority of S2 stars are forming a prominent stream feature through the Galactic plane, a few stars with comparable action variables are also found outside of the main stream. This could be the result of phase mixing and the trace of different wraps of the stellar stream, as the actions of a star are effectively immune to the phase mixing.

Figure 1. Two-dimensional projections of 52 revised SDSS-*Gaia* S2 member stars into the Galactic (X,Z) and (Y,Z) planes. The location of the stars with high-resolution analysis (stars) and SDSS low-resolution analysis (squares) are marked in red. The arrows indicate the individual motions. The Sun and its motion are marked as a yellow star and arrow. The grey line marks the Galactic plane at Galactic $Z = 0$ kpc.

Figure 2. Orbital parameters and the actions of S2 member stars. 52 revised SDSS-*Gaia* stars are marked as stars (high-resolution analysis) and squares (SDSS low-resolution analysis). A violet ellipse marks the 4σ range of a Gaussian model fitted for SDSS-*Gaia* S2 stars in the orbital parameter space. 6 APOGEE stars from [Yuan et al. \(2020\)](#) and 12 stars from [Roederer et al. \(2010\)](#) are marked as circles and triangles. For these 18 stars, the secure members based on the revised kinematics are marked with filled symbols and the rest are marked with unfilled symbols.

2.2 Literature Survey for S2 Members with Spectroscopy

We can also use this set of high quality members to identify other S2 stars from the literature with chemical data. In particular, we searched through the 12 S2 members with high resolution spectroscopy claimed by [Roederer et al. \(2010\)](#) and the 6 S2 members with APOGEE spectroscopy found by [Yuan et al. \(2020\)](#).

The kinematics of these stars are revised with *Gaia* DR2 astrometry and the distance estimates from [Anders et al. \(2019\)](#). The public software package AGAMA ([Vasiliev 2019](#)) is used for computing the action variables and orbit integration (see, [Myeong et al. 2019](#), for more detail). We adopt an axisymmetric gravitational potential model ([McMillan 2017](#)) which consists of a bulge, thin, thick and gaseous discs, and an NFW halo as the Milky Way.

Fig. 2 shows these objects in the planes of action (J_R, J_ϕ, J_z), orbital inclination i and eccentricity e . The orbital parameters of the 52 SDSS-*Gaia* S2 stars are used as a reference to revise the membership of these 18 literature

stars. A Gaussian model is fitted for these reference stars in the orbital parameter space. For our study we consider the stars within the 4σ range of this Gaussian model as the secure S2 member stars.

We retain 10 of these stars as safe S2 members – 7 from [Roederer et al. \(2010\)](#) and 3 from [Yuan et al. \(2020\)](#). They are shown as the filled triangles and circles in Fig. 2 and listed in Table 1. The remaining stars, shown as unfilled symbols, are not as tightly clustered around the high quality S2 sample.

3 OBSERVATIONS AND DATA REDUCTION

Our spectroscopic follow-up sample is built from three different sources. The first is Very Large Telescope (VLT) observations with the Ultraviolet and Visual Echelle Spectrograph (UVES) ([Dekker et al. 2000](#)) and X-SHOOTER ([Vernet et al. 2011](#)). This sample comprises 5 S2 members, albeit with lower signal-to-noise ratio (S/N) than originally

anticipated because of weather conditions. We took advantage of the recent start-up of operations of the new High Optical Resolution Spectrograph (HORuS Peñate et al. 2014) at the Gran Telescopio Canarias (GTC) to obtain data on 2 further objects. Finally, we re-observed 1 S2 object with the second generation Low Resolution Spectrograph (Chonis et al. 2014, LRS2-B) at the Hobby-Eberly Telescope (HET). The high quality data from LRS2-B allowed us to derive elemental abundances. The 7 stars for which we have acquired data are listed in Table 2.

3.1 VLT observations

Three of our targets (J0026+0037, J0049+1553, and J0206+0435) were observed with UVES at the 8.2 m VLT Kueyen Telescope in three observing blocks (OBs) of one hour in service mode during two different nights, 2019 Aug 2nd and Aug 28th under program ID 0103.B-0398(A). A 1''2 slit was used with 1×1 binning in grey sky conditions and an airmass of ~ 1.4 . Our settings used dichroic #Dic1 (390+580) and provided a spectral coverage between 330 and 680 nm. We corrected each spectrum for the barycentric velocity. The average signal-to-noise per pixel in the spectra was ~ 15 , 30 and 35 at 390, 510 and 670 nm respectively. The resolving power for this set up is $R \sim 45,000$ for the blue part of the spectrum (330 – 452 nm) and $R \sim 41,500$ for the red (480 – 680 nm). The seeing was 0''95 during the first and second OB and 1''05 in the third one. The data were reduced using the REFLEX environment (Freudling et al. 2013) within the ESO Common Pipeline Library.

Two more targets (J0007-0431 and J2345-0003) were observed with X-SHOOTER during 2019 Aug 29th, and Sep 24/26th under program ID 0103.B-0398(B). Due to the relative faintness of these targets, three OBs of one hour each were allocated but only one per target were finally carried out. The second target has an additional half-time exposure that was aborted due to weather restrictions. We combined both spectra after barycentric corrections. Grey time, a maximum airmass of 1.3 and seeing of 1'' were the observational conditions. We used slit widths of 0''8, 0''9 and 0''9 (for UVB, VIS and NIR) leading to $R \sim 6200$, 7400 and 5400 respectively. The average S/N obtained per pixel in stare mode was 30, 45, 40 at 390, 510 and 670 nm respectively. The data were reduced by the ESO staff, and retrieved through the Phase 3 query form.

3.2 GTC observations

The observations with HORuS¹ on the 10.4-m GTC were performed in two different periods. Two 1800 s exposures of J0808+2418 were taken during the commissioning of the instrument, in 2018 Dec 12th. In addition, four 1800 s exposures for each of J0808+2418 and J0929+4105 were taken in queue mode in the period 2019 Nov 18th-Dec 18th, under program 133-GTC130/19B.

HORuS uses a 3×3 Integral Field Unit (2.1×2.1 arcsec²) with microlenses on both ends of the fiber link that feeds

Figure 3. Upper: Kiel diagram, colour-coded by $[\text{Fe}/\text{H}]$ of S2 members from SEGUE, BOSS, APOGEE and LAMOST spectra analyzed with FERRE. GAIA isochrones for a wide metallicity range and different ages from 14 to 11 Gyr (dashed lines) are also shown, together with a representative error bars. Lower: The metallicity distribution function (MDF) for S2.

the spectrograph from the Nasmyth focus. The instrument provides a resolving power of $\sim 25,000$ and almost continuous coverage between 380 and 690 nm. We used 8×2 binning to achieve a S/N of 40 at 510 nm for J0808+2418 and J0929+4105 in the coadded spectra. Data reduction was done using version X of the chain², which performs bias and flatfield correction, order tracing, extraction and wavelength calibration.

3.3 HET observations

Low-resolution observations were done in queue mode (Shetrone et al. 2007) filling some gaps in the scheduled program devoted to a different project. LRS2-B uses a 12×6 fibre Integral Field Unit and its two arms cover from 370-470 and 460-700 nm at resolving powers of 1900 and 1100 respectively. J0206+0435 was observed from 2019 Jan 16th to 2019 Feb 27th under programmes UT18-3-001 and UT19-1-005. Four spectra of 1800 s were taken per object with the same setup. The LRS2 spectra were reduced with the HET pipeline panacea³. Then we applied by heliocentric correction, coadded and combined the four individual exposures leading to an average S/N of 150 at 390 nm.

4 ANALYSIS

Myeong et al. (2018a,b) took the stellar parameters, T_{eff} , $\log g$ and $[\text{Fe}/\text{H}]$ from the SDSS and LAMOST automatic pipelines. For very metal-poor (VMP) stars, different levels of carbon-enhancement in the stellar atmosphere affect significantly the opacity of each layer. This effect is not included in the SDSS or LAMOST pipelines. For the sake of consistency, we re-derive T_{eff} and $\log g$ from the original low-resolution SDSS and LAMOST data (see table 2). With these quantities in hand, we compute elemental abundances from both low- and high-resolution spectra. This is the most suitable way to homogenize – as far as possible – the results of this multi-instrument program.

4.1 Low-resolution analysis

4.1.1 Stellar parameters

Aguado et al. (2017a,b) provided a way to analyze low-resolution data from metal-poor stars in large spectroscopic surveys. We follow this methodology for the SDSS⁴ and LAMOST⁵ data, downloading the S2 members from the online database. Then we shift the spectra to the rest-frame using a cross correlation function (CCF) and templates extracted from the grid of synthetic models published by Aguado et al. (2017b). The overall quality of the spectra is high, except for few objects with clear problems. For example, LAMOST J0808+2418 shows an strong artefact spanning 50 nm in the blue part. We then mask part of that region prior to analysis.

Extending the work of Aguado et al. (2017b), we use a grid of synthetic models with limits: $4500 \text{ K} < T_{\text{eff}} < 7000 \text{ K}$, $1.0 < \log g < 5.0$, $-4.0 < [\text{Fe}/\text{H}] < +0.5$, $-1.0 < [\text{C}/\text{Fe}] < +4.0$. Then, we normalize the spectra using a running mean filter of 30 pixels. The FERRE⁶ code (Allende Prieto et al. 2006) is able to derive simultaneously stellar parameters by cubic-B  zier interpolation between the nodes of the grid. We selected the Boender-Timmer-Rinnoy Kan (BTRK, Boender et al. 1982) algorithm to minimize the solution

⁶ FERRE is available from [http://github.com/callendeprieto/ferre](https://github.com/callendeprieto/ferre)

function. An average metallicity is derived in this way together with stellar parameters and $[\text{C}/\text{Fe}]$. The analysis is summarized in Table 2 (the complete table is available in the Appendix B1). The upper panel of Fig. 3 shows the Kiel diagram for the high quality S2 sample, colour-coded by $[\text{Fe}/\text{H}]$. The lower panel shows the metallicity distribution function with the characteristic sharp peak at $[\text{Fe}/\text{H}]=-2$.

4.1.2 Elemental abundances

The grid of synthetic models does contain $[\text{C}/\text{Fe}]$ as a free parameter. With this methodology, we can use all the carbon information in the entire spectra. Aguado et al. (2016, 2019a) provide prescription to derive carbon abundances in metal-poor stars from low-resolution data, depending on T_{eff} and the quality of the spectra. We apply those recipes and derive carbon abundances for more than 75% of the sample with an average uncertainty of 0.2 dex (see Table 2).

We also use the FERRE Spectral Windows (FESWI, Aguado et al. 2020, in prep.) to derive Mg, Ca, and Ti when possible. In general, for VMP stars, the magnesium triplet is detectable at S/N higher than 40-50, sometimes even lower. This makes it possible to derive magnesium abundance by just masking the MgIb triplet region ($\sim 5175\text{\AA}$) and re-running FERRE assuming the stellar parameters derived in Section 4.1.1. A visual inspection of the quality of the fit is used to weed out unreliable ones. We provide magnesium abundances for $\sim 80\%$ of the sample with an average uncertainty of 0.25 dex. The same procedure is followed for Ca I at 4226.7\AA and Ti II at 3913.4 , 4307.8 , 4443.8 , and 4468.4\AA . We derive these species in 60%, 22% of the cases, with a medium uncertainty of 0.30 and 0.35 dex, respectively. Despite the modest accuracy, this provides a valuable collection of elemental abundances to explore the chemistry of S2. In addition, a program of low-resolution but high S/N (~ 150) observations was done with the LRS2 spectrograph at HET. The high quality of this data allowed us to measure for an extra object up 8 elements including C, Mg, Al, Ca, Ti, Fe, Sr and Ba also with moderate accuracy.

4.2 High Resolution Analysis

High resolution X-SHOOTER, HORuS and UVES observations allow us to derive up to 20 different chemical species. The analysis is again carried out with the FERRE Spectral Windows (FESWI, Aguado et al. 2020, in prep.), but applied in a more precise way. We measure chemical abundances of C, Li, Na, Al, Sc, the α -elements Mg, Si, Ca and Ti, iron-peak elements V, Cr, Mn, Fe, Co, Ni, and the n-capture elements Sr and Ba. We note that lithium is discussed in Appendix A.

We first identify isolated metallic absorptions, discarding some blends that could lead to wrong detections. Then we build a set of spectral windows, one per target and chemical element. The width of each window is 2.5 times the full width at half maximum (FWHM) centered in the central wavelength of each line. Both the core and the wings of the lines are covered by the spectral windows, leaving the rest of the spectrum masked. Then, we run FERRE fixing the T_{eff} and $\log g$ values from Table 2 to derive carbon and metallicity only within each spectral window. This ensures that we

Figure 4. A comparison between the high- and low-resolution (arbitrarily shifted by 1 in the y-axis) analysis performed for J0206+0435. Upper and middle panels show the H_γ region together with Mg I absorptions and a detail of several Fe I and Sr II lines around 4060\AA respectively. Both UVES and LRS2 spectra are normalized using a running mean filter (black lines) and the best FERRE fit is also shown (blue lines). Red dashed lines delimit the spectral windows where the analysis was performed. The bottom panel shows the difference between both analyses for several elemental abundances. Error bars represent only the low-resolution uncertainties.

are able to fit all the chemical signals in the data at the same time rather than just performing a line-by-line analysis. The method is robust against possible trends of abundances with wavelength (see e.g., Roederer et al. 2014, and references therein). Finally, we can measure lines even in the low S/N end of the data if large enough number of lines cross the spectra, such as for Fe or Ti.

We detect in all cases strong absorption of Mg I (the triplet around $\sim 5170\text{\AA}$), Ca I (4226 and 4425\AA) and Ti II (3759 and 3761\AA), and 5 other persistent lines for Mg I, 7 for Ca I and 20 for Ti II. In Fig. 5, we show an example of

Figure 5. A narrow region of the X-SHOOTER, HORuS and UVES spectra of J0007–0431, J0929+4106, and J0026+0037 respectively around the Mg I B area (black lines) together with the best FERRE fit (blue lines) only calculated over the spectral windows delimited by red dashed lines. The normalization was performed using a running mean filter.

two Mg lines detected and fitted within the FERRE spectral windows from data of the three employed instruments. We also report Si I from UVES and X-SHOOTER data and some lines of Ti I only from UVES. Carbon abundances are derived in the same way as in Section 4.1 without the need to use spectral windows but measuring the CH across the entire spectra, especially through the G-band at 4285–4315 Å as do the authors in [González Hernández et al. \(2020\)](#). Neither O nor N lines are detected. The optical spectra contain plenty of iron-peak features V I, Cr I, Mn I, Co I, and Ni I. However, we only detect Co and Ni in the bluer part of the UVES spectra. The sodium absorptions at 5889 and 5895 Å are clearly detected, even at the moderate S/N of the two X-SHOOTER spectra. We also identify two Al I absorptions at 3944 and 3961 Å. Sr and Ba show the strongest absorptions from any other neutron-capture elements in the optical. We measure Sr II at 4077 and, sometimes 4215 Å. The most commonly used persistent lines of Ba II are 4554, 4930, 5853, 6141, and 6496 Å. With HORuS, we cover the two bluer lines, but with UVES, the deepest one at 4554 Å is out of the spectral coverage. We do not clearly detect Ba in the two X-SHOOTER objects but a robust upper limit is provided from the 4554 Å line. Unfortunately, neither Y nor Eu is detected due to the weakness of those features combined with our modest S/N. In Fig. 6, we show snippets of

n-capture elements (Sr and Ba) lines together with the best fit from FERRE for the three instruments.

The elemental abundances in our work are derived assuming one dimensional local thermodynamic equilibrium (1D-LTE). This assumption simplifies the modelling of stellar atmospheres and the spectral synthesis of line profiles. It also has the advantage that most of the codes and computed models are public and so easily tested by other authors. An important part of the S2 analysis is based in the determination of α -abundances. Mg and Ca NLTE correction tend to be small (< 0.1 dex) for FGK stars ([Mashonkina et al. 2007; Mashonkina 2013](#)) at this metallicity regime. However, Ti corrections can be up to ~ 0.2 dex ([Sitnova et al. 2016](#)). In addition, the average S/N of our high-resolution data is moderate ($\sim 25 - 30$) or even poor in the bluer parts of the spectra. Nonetheless, taking into account our sample is mainly comprised of VMP dwarf stars with similar T_{eff} (~ 6100 K) our accuracy is good enough to detect chemical trends. We also use the online tool INSPECT⁷ (see e.g., [Lind et al. 2012; Amarsi et al. 2016](#), and references therein) to check Li NLTE corrections are also within < 0.1 dex. The effect of the 1D-TE assumption on n-process elements in metal-poor stars is not well studied. For Sr and Ba, the corrections could be quite significant ([Andrievsky et al. 2011; Korotin et al. 2015; Gallagher et al. 2020](#)) and are probably in the range 0.02–0.20 dex. However, [Mashonkina et al. \(2017\)](#) derived slightly smaller NLTE corrections for Sr and Ba for a range of metal-poor dwarf galaxy members.

4.3 High versus low resolution analyses

To perform a detailed chemical analysis, costly high resolution observations are needed. However, it is possible to work with low-resolution data if we focus a few elements such as α -elements, Fe, Sr and Ba, though the accuracy is moderate. Here, we present a comparative analysis of J0206+0435 observed with both UVES and LRS2.

We detect 370 absorption lines (including 276 Fe I lines) in the J0206+0435 UVES spectra, while only 43 lines are clearly detected in the LRS2 one (31 of them are Fe I). We only fit in the spectral windows in which we do identify a line. So, the available metallic information in low resolution data is much more limited due to two main reasons: 1) the much smaller number of detections and 2) the smaller number of pixel per line the spectra contain. Fig. 4 shows two spectral ranges with several metallic lines, together with the spectral windows (red dashed lines) used during the analysis. Defining the metallic sensitivity for a certain line as the ability to vary the shape and the FWHM with the abundance of this particular element for a given T_{eff} and $\log g$ it is clear that there is a large difference between the high- and the low-resolution data. However, it is also important to note there is substantial information within the LRS2 high S/N data. In particular, α -elements such as Mg, Ca, and Ti and, sometimes, Si can be detected. Finally, the large offset we find in Al and Sr (See Fig. 4) recommends to not rely in these abundances. Since these fits in middle panel seem to be good enough we will study this issue in future work.

⁷ Non-LTE data obtained from the INSPECT database (version 1.0), available at <http://inspect.coolstars19.com/>

Figure 6. A narrow region of the X-SHOOTER, HORuS and UVES spectra of the seven stars with high-resolution data respectively around the Sr II at 4077.7 Å and Ba II at 4934.0 Å areas (black lines) together with the best FERRE fit (blue lines). Upper limits are coloured in red.

4.4 The S2 subsamples from the Literature

4.4.1 APOGEE

Three S2 members selected from Yuan et al. (2020) have APOGEE DR14 (Gunn et al. 2006; Holtzman et al. 2018) information. These objects were analyzed by the automatic pipeline ASPCAP (García Pérez et al. 2016) that also uses spectral windows to perform elemental abundances analysis from the infrared H-band. We retrieved the data using the online tool⁸ and obtained the stellar parameters together with metallicity and chemical abundances.

Following the recommendations of APOGEE (Holtzman et al. 2018), we use only calibrated data and discard the titanium abundances as their reliability is uncertain. In addition, we find the fits for Na, V, Cr and Co abundances to be untrustworthy due the weakness of their absorptions in the NIR. However, for C, Mg, Al, Si, Ca, Mn and Ni, we accept the ASPCAP values. A summary of the APOGEE S2 members is given in Table 1, while individual abundances are given in Table B2.

4.4.2 Roederer et al. (2010)

Seven stars already observed and analyzed by Roederer et al. (2010) are S2 members. They used the MIKE spectrograph at the Magellan telescope and provide up to 46 elemental abundances.

For this paper, we assume their stellar parameters, together with abundance ratios. Two stars, CS 22876-040 and CS 29513-031, are subgiants. However, the other five stars are in a more evolved phase: BD+30 2611, CD-36 1052, HD 128279, and HD 175305 are on the red giant branch while HD 119516 seems to be close to the red horizontal branch, at least as judged from Fig. 3. These stars – together with those from APOGEE – help to trace the evolution of S2 as a galaxy. A summary of the stellar parameters associated with these S2 members are listed in Table 1, while the elemental abundances can be extracted from Table 7 of Roederer et al. (2010).

4.5 Derived uncertainties

The error bars of the low-resolution analysis shown in Table 2 are derived by adding in quadrature the internal FERRE uncertainties (statistical error, derived by inverting the matrix curvature) and the possible systematic errors of the stellar parameters of the observed stars. Those systematics are taken as $\Delta T_{\text{eff}} = 100$ K, $\Delta \log g = 0.5$, $\Delta [\text{Fe}/\text{H}] = 0.1$ dex, and $\Delta [\text{C}/\text{Fe}] = 0.2$ dex. The rationale for these choices are given in Allende Prieto et al. (2014) and Aguado et al. (2017b).

The error bars for the individual chemical abundances from high-resolution data analysis also are derived in a similar way. The typical internal FERRE uncertainty for the UVES data varies between 0.02 – 0.10 dex for iron and neutral titanium respectively. For the HORuS data, the range is 0.07 – 0.15 dex and for X-SHOOTER, 0.04 – 0.12 dex. As we are presenting elemental abundances from different origins, we consider additional sources of systematic errors. First, the 1D-LTE assumption introduces a deviation, as discussed in

⁸ <https://www.sdss.org/dr16/irspec/aspcap>

Sec. 4.2. However, the effect on measurements is different in the optical range than in the infrared (H-band). Even if NLTE correction are potentially small, the fact that they could be different in different ranges of the spectrum is an additional source of uncertainty in our comparative analysis. Secondly, we are using different instruments located on different telescopes and this necessarily introduces a hard-to-quantify bias when deriving abundances from different lines. Thirdly, our synthetic models are computed adopting a microturbulence value of $\xi = 2.0$ km/s. The observed microturbulence of dwarf stars tends to be closer to a $\xi = 1.5$ km/s value (Cohen et al. 2004; Barklem et al. 2005). This could lead to an additional uncertainty, estimated to be lower than 0.04 dex in metallicity. Combining these possible sources of systematics, we find a systematic error that is at the level of the statistical one 0.03–0.12 dex. The errors given in Tables 3 and 4 include both the statistical and systematic effects.

5 DISCUSSION

Figure 7 gives abundance ratios of the elements available as part of our study split into several groups. We start with carbon as a representative of the CNO group. The light elements are split into two sub-groups, with even and odd atomic number. The odd- z group is represented by Na, Al and Sc, while the even- z elements are Mg, Si, Ca and Ti. These are followed by the iron-peak group which includes V, Cr, Mn, Co and Ni. Finally, the last two panels present the abundance patterns of the two neutron-capture elements, Sr and Ba.

Remarkably, 54 out of 62 stars in our sample are main sequence/turn-off stars with $\log g > 3.5$, offering an unique view as to the original chemical composition of the environment from they were formed. However, for the other 8 evolved stars, there are possible mixing effects that may alter their chemical signature of lighter elements, such as Li, C or Na. Surface composition of an FGK star is considered an accurate guide to the chemistry of the gas from which they were formed. Once the star leaves the main sequence towards the red giant branch, dredge-up process cause changes in the convective envelope. Variations in CNO abundances are firstly small, but could be altered significantly in more evolved evolutionary phases (Becker & Iben 1980; Spite et al. 2005). For instance, Placco et al. (2014) studied the carbon abundance problem in giants and provided models to estimate the amount of carbon converted in nitrogen via CN cycle (Charbonnel 1995).

5.1 The beginning of star formation: to knee or not to knee?

The star-formation efficiency at the beginning of dwarf’s life can be gleaned from the evolution of the abundance ratio of α -elements with even atomic number to those in the iron peak group. Elements in both groups can be synthesized either in the interiors of massive stars or in the explosions of lower-mass stars in supernovae of type Ia. However, massive star explosions (core-collapse SN) are less efficient in delivering the iron peak material to the inter-stellar medium compared to SNe Ia as some of the stellar core collapses to form the dark remnant. Given that massive stars live much

shorter lives than the SNe Ia progenitors, the ISM enrichment in the first ~ 1 Gyr of the galaxy’s life is driven by the massive star nucleosynthesis dispersed by core-collapse SN (CCSN). Accordingly, the oldest stellar generations are expected to exhibit an enhancement in α -elements compared to iron (e.g. Nomoto et al. 2013). Once white dwarfs start to explode in supernova of type Ia, copious amounts of heavier elements are delivered to the ISM (see e.g. Iwamoto et al. 1999), thus decreasing the α over-abundance. The delay in the onset of SNe Ia explosions compared to CCSN provides a natural clock: the efficiency with which the galaxy formed its stars in the first ~ 1 Gyr of its life can be judged by the maximal metallicity $[\text{Fe}/\text{H}]$ before the decrease in α -abundance (Tinsley 1979; Matteucci & Brocato 1990; Gilmore & Wyse 1991; McWilliam 1997; Matteucci & Recchi 2001; Matteucci 2003).

A predicted pattern consisting of a roughly constant over-abundance of $[\alpha/\text{Fe}] \sim 0.4$ at low $[\text{Fe}/\text{H}]$ and a steady decline of $[\alpha/\text{Fe}]$ to Solar value beyond a characteristic metallicity achieved by the galaxy before the onset of SNe Ia sometimes called an “ α -knee” has been observed in several Galactic dwarf satellites, both intact and disrupting (see Venn et al. 2004; Tolstoy et al. 2009; Letarte et al. 2010; Lapenna et al. 2012; Lemasle et al. 2012; de Boer et al. 2014; Nidever et al. 2020). The exact shape of the knee depends on the physical conditions governing the dwarf’s early star formation including chemical yields, the initial mass function (IMF), star-formation rate, as well as temperature, density, inflow and the outflow rates of the gas (e.g. Matteucci & Brocato 1990; McWilliam 1997; Kobayashi et al. 2006; Lanfranchi & Matteucci 2007a; Schönrich & Binney 2009; Revaz & Jablonka 2012; Romano & Starkenburg 2013; Vincenzo et al. 2016; Côté et al. 2017; Andrews et al. 2017; Weinberg et al. 2017; Fernández-Alvar et al. 2018).

As displayed in Figure 7, out of four α -elements available, Mg and Ca show some evidence for the existence of a “knee” in the S2 stream. Although nucleosynthetic pathways of hydrostatic (O, Mg) and explosive (Si, Ca and Ti) α -elements are not the same it is common to combine their abundances to improve the detection quality of the α -pattern. Accordingly, Figure 9 shows a combination $([\text{Mg}/\text{Fe}] + [\text{Ca}/\text{Fe}] + [\text{Ti}/\text{Fe}])/3$ as a function of $[\text{Fe}/\text{H}]$ for both the S2 members (large red symbols) and stars from other galaxies (small colored points). The S2 measurement shown as a square at $[\text{Fe}/\text{H}] = -3.0$ is the most metal-poor star from SDSS data where only Ca is clearly detected at $[\text{Ca}/\text{Fe}] = +0.4$. The other square symbol at $[\text{Fe}/\text{H}] = -2.0$ is the average between 9 S2 members with SDSS spectroscopy and with Mg, Ca and Ti abundances. These stars are within the metallicity range of 0.07 dex but with large α uncertainties ($\sim 0.30 - 0.35$) as is shown in Fig. 7. The error bar for this representative point is the dispersion of α -values. Finally the filled circles correspond to the S2 members observed with APOGEE. Note however that only Mg and Ca abundances are used for these stars since Ti values are not reliable (García Pérez et al. 2016) so we compute alphas as $([\text{Mg}/\text{Fe}] + [\text{Ca}/\text{Fe}])/2$. Values of α abundance for 99 giant stars in Sculptor obtained with high-resolution spectroscopy by Hill et al. (2019) are shown as small cyan circles. Additionally measurements for the field stars in the Milky Way are given as grey dots. Thick black line shows an approx-

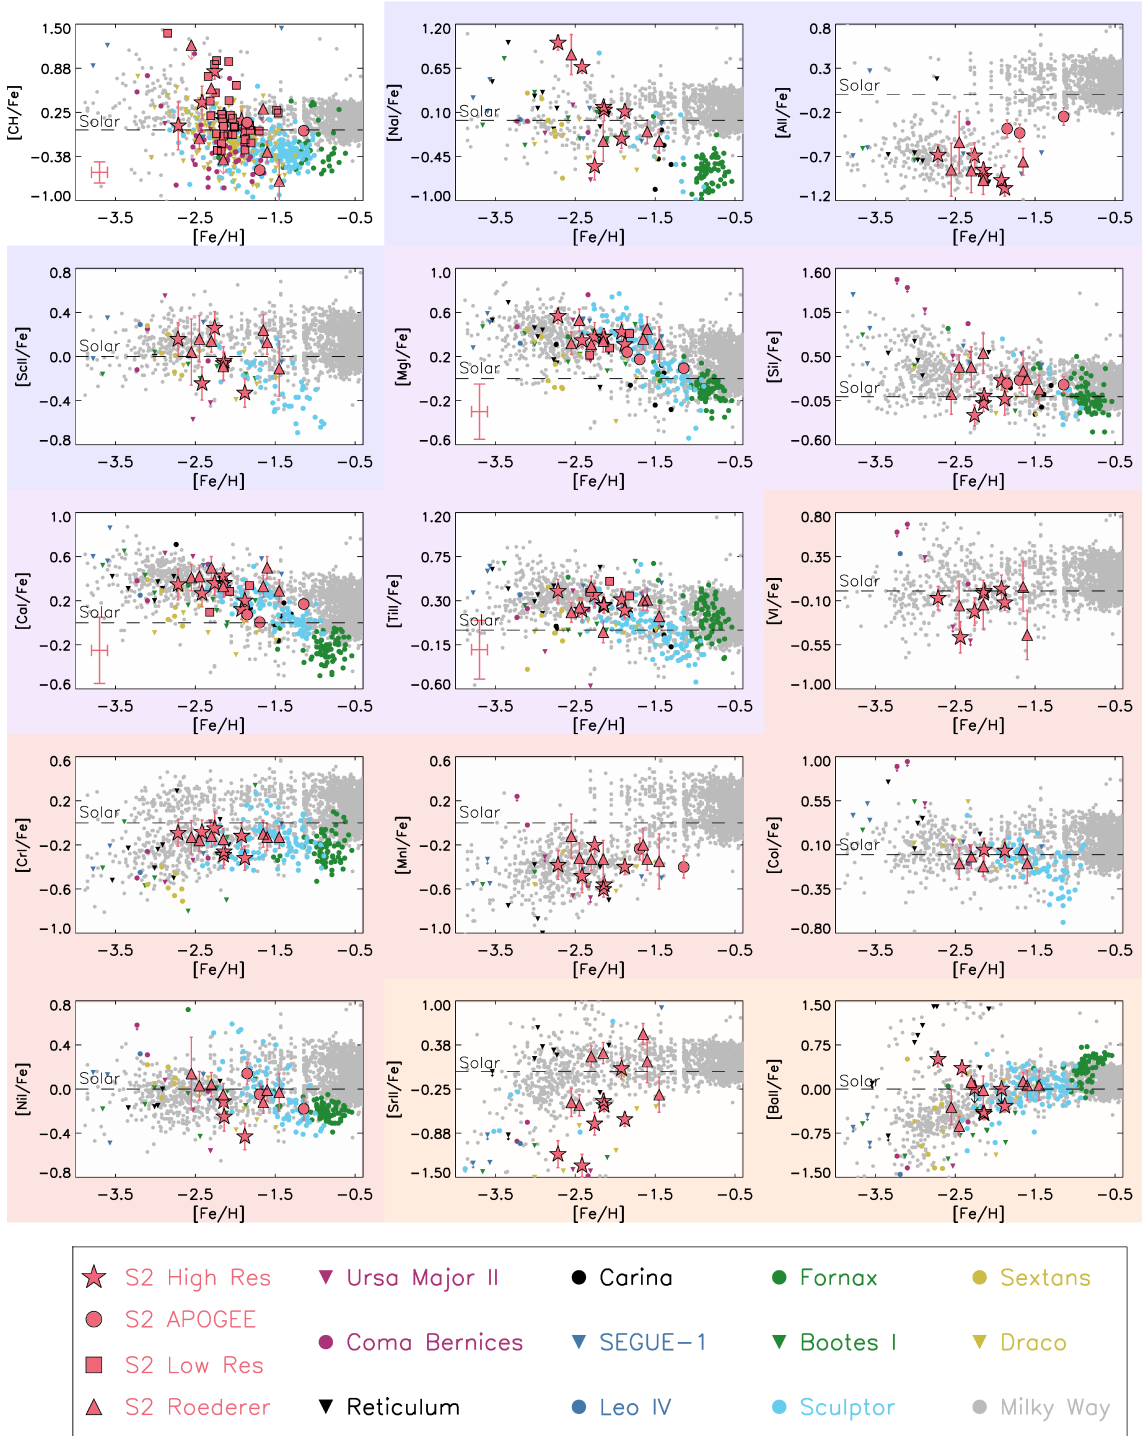

Figure 7. Abundance ratios ($[X/Fe]$) as a function of metallicity ($[Fe/H]$) for various elements detected in S2 from our high-resolution program (red filled stars), Roederer et al. (2010) (red filled triangles), APOGEE survey (red filled circles) and our SDSS low-resolution analysis (red filled squares). The latest are grouped in bins of ~ 0.25 dex in metallicity and representative error bar is shown. We also show elemental abundances from other ultra faint and classical dwarf galaxies from literature: Ursa Major II (Frebel et al. 2010b; Kirby et al. 2015), Sextans (Aoki et al. 2009a), SEGUE-1 (Norris et al. 2010d; Frebel et al. 2014), Sculptor (Geisler et al. 2005; Kirby & Cohen 2012; Jablonka et al. 2015; Kirby et al. 2015; Simon et al. 2015; Skúladóttir et al. 2015; Hill et al. 2019), Coma Bernices (Frebel et al. 2010b), Draco (Cohen & Huang 2009; Shetrone et al. 2013; Kirby et al. 2015), Carina (Koch et al. 2008a), Bootes (Norris et al. 2010a; Lai et al. 2011), Leo IV (Simon et al. 2010), Reticulum II (Ji et al. 2016c), and Fornax (Letarte et al. 2010; Kirby et al. 2015; Letarte et al. 2018). For comparison we also show a those of halo (Aoki et al. 2007; Bonifacio et al. 2009; Aoki et al. 2012; Bonifacio et al. 2012; Cohen et al. 2013; Aoki et al. 2013; Yong et al. 2013a,b; Roederer et al. 2014; Aguado et al. 2016) and disc stars are shown (Bensby et al. 2014; Buder et al. 2018). The background colours group different families: odd-, α -, iron-peak and n-capture elements. Solar abundance references are shown.

Table 3. Abundances, ratios, errors and number of detected lines for individual species derived with UVES.

imate model of the Milky Way chemical evolution with a knee starting at the metallicity $[Fe/H] \sim 1.0$.

Figure 9 demonstrates clearly the presence of the plateau $[\alpha/Fe] \sim 0.4$ for S2 stars with metallicities $[Fe/H] < -2$. At higher metallicities, $-2 < [Fe/H] \leq -1.5$ (our sample contains only one candidate member star with a metallicity higher than that), there are hints of a decline to $[\alpha/Fe] \sim 0.2$. This can be compared to the chemical trends observed in the Sculptor dwarf galaxy, which reaches the α plateau at a very similar metallicity of $[Fe/H] \sim -2$. In this Figure, the α tracks of S2 and Sculptor appear aligned, but S2's MDF is clearly truncated around $[Fe/H] \leq -1.2$ while Sculptor's continues

to higher metallicities and negative $[\alpha/Fe]$ ratios (see discussion in [Hill et al. 2019](#)). It appears that at the outset, the star-formation in the two galaxies may have proceeded in a similar fashion, but was sharply truncated in the S2's progenitor as the dwarf was accreted and pulled apart by the Milky Way.

While Figure 9 points to similarities between Sculptor and the S2 progenitor in terms of the average $[\alpha/Fe]$ evolution, a careful look at the trends of individual α -elements with iron rouse suspicion. First, $[Mg/Fe]$ is very flat, and save for the two stars at the extremes of the metallicity distribution, is consistent with a constant abundance ratio. Looking

Figure 8. $[\text{Mg}/\text{Fe}]$ and $[\text{Ca}/\text{Fe}]$ versus $[\text{Fe}/\text{H}]$ observed in S2 compared with the predictions of the chemical evolution model by [Lanfranchi & Matteucci \(2004\)](#). Symbols and references are the same as in Fig. 7. Three different evolution models per row are shown. *Top:* SFR with $\nu = 0.3, 0.1, 0.05 \text{ Gyr}^{-1}$. *Bottom:* galactic wind efficiency with $\omega_i = 1, 2, 3$ See 5.1.1 for discussion.

at Ca, several stars at higher metallicities appear to exhibit lower values of $[\text{Ca}/\text{Fe}]$. However, the picture is confused by the presence of an equal number of stars remaining on the plateau at the same metallicity. Thus, the only conclusion which can be drawn with certainty is that the $[\text{Ca}/\text{Fe}]$ spread increases with $[\text{Fe}/\text{H}]$. The clearest difference between S2 and Sculptor is visible in the trend of $[\text{Ti}/\text{Fe}]$ with metallicity. Across the $[\text{Fe}/\text{H}]$ range sampled by the S2 stars, Ti abundance is observed to be affected by the SN Ia contribution (as seen in Sculptor [Hill et al. 2019](#)). Note, however, that for the S2 members, $[\text{Ti}/\text{Fe}]$ remains flat and systematically above that of the Sculptor stars which also show a downward slope. These individual abundance trends paint a picture of a dwarf galaxy whose chemical enrichment was barely affected by the SN Ia pollution.

5.1.1 Chemical evolution models

Aiming to quantify the chemical evolution of S2, we compare derived $[\alpha/\text{Fe}]$ abundance ratios with the results of a detailed chemical evolution model as presented in [Lanfranchi & Matteucci \(2004\)](#). As described in [François et al. \(2004\)](#), these models take into account stellar lifetimes, the energy of stellar winds and supernovae

types II and Ia, alongside the nucleosynthetic yields from [Thielemann et al. \(1996\)](#); [Nomoto et al. \(1997\)](#). By solving the basic chemical evolution equations given by [Tinsley \(1980\)](#) and [Matteucci \(1996\)](#), the model is able to predict the time evolution of the individual α -element abundances. The main parameters of the code are the star formation efficiency (ν) and the galactic wind efficiency (ω_i) (i.e. the rate of the gas loss), both constrained by the data. SFR and wind efficiency are adjusted to fit the observed values, whereas the initial mass of the galaxy has little impact in the results of the abundance ratios, but it is indirectly taken into account through the SFR. A combination of a low star formation efficiency and a high wind efficiency is required to explain the abundance ratios of α -elements in classical Dwarf Spheroidal Galaxies, especially the observed lowest values ([Lanfranchi & Matteucci 2004](#)). This is the consequence of the time-delay interpretation ([Matteucci 2012](#)), predicting that in regime of low SFR the decrease of the $[\alpha/\text{Fe}]$ ratio is steeper and occurring at lower metallicity. Supernovae explosions and winds from massive stars are important sources of galactic gas outflows, a crucial feature in the evolution of Dwarf Spheroidal Galaxies ([Lanfranchi & Matteucci 2003, 2007b](#)). Galactic winds occur when the kinetic energy of the gas is equal or higher than the binding energy of the gas. As a result, chemically enriched gas and dust are expelled from the galaxy, thus decreasing the SF rate and changing the evolution of abundance ratios, in particular $[\alpha/\text{Fe}]$.

Figure 8 shows S2 evolutionary models for Mg and Ca and the best matches for ν and ω_i . The top row shows the best fits for star formation efficiency. One can notice that the adopted range of values can account for almost all the data implying that the SF in the system is compatible with an efficiency $\nu = 0.05 - 0.3 \text{ Gyr}^{-1}$, with $\nu = 0.1 \text{ Gyr}^{-1}$ as the best value. That means that S2 is characterized by a star formation ~ 10 times lower than that in the Solar neighbourhood ($\nu = 1.0 \text{ Gyr}^{-1}$ [Chiappini et al. 1997](#)). Using the same models [Lanfranchi & Matteucci \(2004\)](#) found that the Sculptor data is best described with a SF efficiency $\nu_{\text{best}} = 0.2 \text{ Gyr}^{-1}$: SF in S2 is similar or slightly slower compared to Sculptor. The difference in the efficiency of the galactic wind, on the other hand, is much higher. Whereas in Sculptor a very high value for the wind efficiency is required, the bottom row of Figure 8 gives values between $\omega_i = 1 - 3$ (with a best value of 2: almost 6 times lower than for Sculptor). This difference means that galactic winds in S2 push away less gas and dust out of the system than in Sculptor, causing also a lower decrease in the SFR. That fact explains why the $[\alpha/\text{Fe}]$ -slope of S2 is less steeper than the Sculptor one shown in Fig. 9.

5.2 Neutron capture elements

The site of n-element production is still under debate (see e.g., [Thielemann et al. 2011](#), and references therein). Evolved AGB stars are environments in which slow-neutron capture could happen ([Busso et al. 1999](#)), leading to galactic enrichment of s-elements such as Sr, Ba and Y ([Travaglio et al. 2004](#)). The s-process also takes place in the helium and carbon burning phase of massive stars ([Käppeler et al. 2011](#)). On the other hand, rapid-neutron capture process occurs in more massive stars via SN II explosions ([Snedden et al. 2008](#)) or more exotic events such as neutron star mergers ([Qian 2000](#)). The majority of the

Figure 9. Combined Mg-Ca-Ti α -element abundances vs metallicity for S2 members. Symbols and references are the same as in Fig. 7. The red square at $[\text{Fe}/\text{H}] = -3.0$ represents the most metal-poor S2 star and the y-axis value is calculated by only the Ca II K line. Red dots from APOGEE data represent Mg-Ca abundance. The red square at $[\text{Fe}/\text{H}] = -2.0$ is a bin containing of 10 Mg-Ca-Ti measurements from SDSS low-resolution data. The dotted-dashed line indicates the solar ratio. The black lines represents the canonical Milky Way chemical evolution with the “knee” starting at $[\text{Fe}/\text{H}] = -1$ when the effect of SN Ia contribution starts to be significant. Due the lower SFR the S2 knee appears at lower metallicities than in the Milky Way. The chemical evolution of S2 is slower than the Sculptor due lower galactic wind efficiency.

halo metal-poor stars show n-process enhancement but – with the remarkable exception of the Reticulum II galaxy (Ji et al. 2016a) – all the dwarf galaxies show clear underabundance in n-capture elements (e.g., Frebel et al. 2010a; Simon et al. 2010; Norris et al. 2010d,b; Frebel et al. 2014; Ji et al. 2016b). This is compatible with the assumption that in the Milky Way, the main channel for n-element is core-collapse supernovae (Qian 2000; Argast et al. 2004), but in less massive dwarf galaxies, the production may be dominated by rare events, such as neutron star mergers (Ji et al. 2016a). Between the rapid and slow flux of neutrons to form heavier elements is the intermediate-process (Cowan & Rose 1977). This i-process likely occurs in the most massive AGB stars with $\sim 7\text{--}10 M_{\odot}$ and could be responsible for n-capture production (see e.g., Jones et al. 2016).

In the bottom row of Fig. 7, we plot the two n-capture elements, Sr and Ba. We see clear Sr underabundance relative to Fe, well below that of the old halo stars. However, S2 shows higher Ba abundances than other dwarf galaxies. The two most metal-poor stars from S2 with high-resolution data, J0808+2418 and J0929+4105, show a very extreme Sr vs Ba ratio, with $[\text{Sr}/\text{Ba}] = -1.68$, $[\text{Sr}/\text{Ba}] = -1.74$ at $[\text{Fe}/\text{H}] = -2.71$ and $[\text{Fe}/\text{H}] = -2.41$ respectively. Fig. 10 shows $[\text{Sr}/\text{Ba}]$ versus $[\text{Sr}/\text{Fe}]$ for both classical and ultra faint dwarf galaxies. The bulk of halo stars show an overabundance of Sr relative to Ba, that is $[\text{Sr}/\text{Ba}] > 0$ (Frebel

Figure 10. N-capture element ratios for S2 members with high-resolution data. Symbols and references are the same as in Fig. 7. Two S2 members J0808+2418 and J0929+4105 show quite unusual n-elements pattern with extremely low $[\text{Sr}/\text{Ba}]$ ratio. See Section 5.2 for discussion.

2010; Cescutti & Chiappini 2014). The spread of the ratio $[\text{Sr}/\text{Ba}]$ in Milky Way halo stars may be explained by fast rotating massive metal-poor stars (Cescutti et al. 2013) in a nonstandard n-process, but this can not explain ratios with $[\text{Sr}/\text{Ba}] < -0.5$ (see e.g., Frischknecht et al. 2012).

However, many dwarf galaxies show even lower n-capture ratios, as is evident from Fig. 10. Both Ba and Sr are typical s-process elements with more than 80% of the Ba in the solar system coming from s-process production (Bisterzo et al. 2014). But, at very low-metallicities $[\text{Fe}/\text{H}] \lesssim -2.8$, there is not expected to be a significant contribution of s-elements from AGB production. Instead, r-process production in high-energy neutron-rich environments is a dominant channel. Although theoretically such low $[\text{Sr}/\text{Ba}]$ ratios could be explained by mass transfer from a binary companion (Gallino et al. 2006) or i-process production in massive AGB (Jones et al. 2016), we consider both scenarios less likely since these two stars do not show clear carbon-enhancement (Abate et al. 2013; Jones et al. 2016). Finally, Frebel & Norris (2015) proposed that a special feature of dwarf galaxies with subsolar $[\text{Sr}/\text{Ba}]$ ratio might that they reflect the composition of the earliest star-forming clouds. We argue that the n-capture pattern in some of the most metal-poor S2 stars could be due to r-process production and potentially reflect the chemical composition of the

pristine gas, polluted only by neutron star mergers or type II supernova. Although the S2 n-pattern shown in Fig. 10 may suggest exotic Sr-Ba production, we emphasise that we only find two stars in the most interesting part of the diagram.

5.3 Other elements

5.3.1 Carbon

The presence of carbon in molecular clouds permits cooling channels allowing low-mass star formation due to fragmentation. [Meynet et al. \(2006\)](#) showed how, in rotating massive stars, internal mixing and stellar winds could be responsible for providing large excesses of CNO to the interstellar medium in early star formation. The fraction of metal-poor stars showing carbon-overabundance increases towards lower metallicities (e.g., [Cohen et al. 2005](#); [Carollo et al. 2012](#); [Yong et al. 2013b](#); [Bonifacio et al. 2015](#)). Different explanations have been proposed, including fallback mechanisms after core-collapse supernovae ([Umeda & Nomoto 2003](#)) and the existence of a core-collapse sub-type that only ejects the outer layers with lighter elements ([Ishigaki et al. 2014](#)). There are also extrinsic explanations, such as significant mass-transfer from a more evolved AGB companion ([Herwig 2005](#)). [Placco et al. \(2014\)](#) showed that the fraction of carbon-enhanced metal-poor (CEMP) in the halo is 25% in the VMP regime ($[\text{Fe}/\text{H}] < -2.0$). According to the classification by [Beers & Christlieb \(2005\)](#), CEMP-no stars are those that show no neutron-capture element enrichment. The oldest relics from star formation are precisely this subclass, in which the carbon enrichment reflects the chemical composition of the cloud they were formed and no mass donation from a binary companion is observed. Since stars in the giant branch convert carbon to nitrogen, to ensure a fair comparison with S2 members, we have selected from the literature, when available, carbon abundances already corrected by this effect ([Placco et al. 2014](#)). That fact makes easier to analyze absolute abundances instead of element ratios even for evolved stars where the mixing process are playing a remarkable roll.

Section 4 presents 62 carbon measurements from S2 members and 63% of them are VMP. Fig. 11 shows the absolute carbon abundance versus metallicity diagram. Some 20% of the VMP stars are found to be CEMP stars. This ratio is in good agreement with the dwarf galaxies in the cosmological simulations of [Salvadori et al. \(2015\)](#). In the case of J0007-0431, we have high-resolution analysis showing no n-process enrichment at all, so this star is classified as CEMP-no star. In the plot, bands are shown marking the regions of the $A(\text{C})$ - $[\text{Fe}/\text{H}]$ diagram in which CEMP-no and the other n-enriched subclasses of CEMP stars reside. The S2 members are located in three different parts of the diagram:

- Carbon-normal $[\text{C}/\text{Fe}] < 0.7$ members: This group represents $\sim 88\%$ of the S2 members and lies below the dotted-dashed line ($[\text{C}/\text{Fe}] < 0.7$).
- CEMP-low members: With $\sim 10\%$ of the stars belonging to this group, these are likely CEMP-no stars as J0007-0431 is.
- CEMP-high members: There is one star (J1252+3001) that shows almost the same carbon abundance as the Sun but more than hundred times less metallic content. This

Figure 11. Carbon abundances $A(\text{C})$ of metal-poor stars as a function of $[\text{Fe}/\text{H}]$ for S2 members. Symbols and references are the same as in Fig. 7. The dotted line is the solar absolute carbon abundance, while the dotted-dashed line is the CEMP limit at $[\text{C}/\text{Fe}] = +0.7$. Thick lines are the approximate levels for low- and high-carbon bands, according to the groups qualitatively described in [Bonifacio et al. \(2015\)](#) and [Yoon et al. \(2016\)](#). S2 members (red circles, stars, squares and triangles according to the source of the data) are located in three different areas of the diagram.

could arise from mass transfer from an AGB binary companion.

We also show in Fig. 11 the carbon distribution function for other dwarf galaxies. With the exception of Segue 1 ([Frebel et al. 2014](#)), most of them have members that are carbon-normal, like the majority of S2 members. However, S2 also has a significant fraction of CEMP-no stars. This suggests, similar to Segue 1, that S2 is indeed a very primitive galaxy with members formed from the pollution of a very few CCSNe. Since Segue 1 members are more metal-poor, we expect that S2 had a slightly faster chemical evolution corresponding to a higher mass system. Interestingly enough, both galaxies do contain at least one strongly carbon-enhanced star that lies in the high band of the diagram. The number of dwarf galaxy members in Fig. 11 that show carbon enhancement and no significant n-process enrichment is quite low (e.g., Figure 1 in [Yoon et al. \(2019\)](#)). However, according to [Salvadori et al. \(2015\)](#), there should be CEMP-no stars in every dwarf galaxy so S2 supports this result.

5.3.2 Aluminium and iron-peak elements

In the upper-row of Fig. 7, we show the Al behaviour of S2 members. This seems to agree with other metal-poor stars in the Milky Way. Low $[\text{Al}/\text{Fe}]$ values are typical signatures of dwarf galaxies, in contrast with globular clusters (GC) ([Cavallo et al. 1996](#)). In addition, the three RGB stars (red circles and triangles) with Al measurement do not show significant Al enhancement but are compatible with the behaviour of dwarf S2 members. That fact confirms the idea that proton-capture process that converts Mg into Al is not reachable at RGB temperatures ([Spite et al. 2006](#)).

Sc and iron peak-elements such as Cr, and Co show compatible trends with other dwarf galaxies. The Co ratio is almost flat with metallicity, whereas Sculptor shows Co de-

creasing with higher metallicity. Finally, V is not very much studied in dwarf galaxies at the time of this writing, but its behaviour in S2 is similar to the halo field stars. However, Mn and Ni show a slightly different behaviour, with higher dispersion with metallicity and the largest overabundance in the iron-peak family. Theoretical studies on SN Ia yields by Kobayashi et al. (2020) show an anticorrelation of α -elements with Mn and lower Ni production in dwarf galaxies. We do not see a Mn trend in Fig. 7 but a clear Ni overabundances in two different sequences is shown.

5.3.3 Sodium and Nickel: a puzzling relation

Sodium, and also nickel production, are moderated by neutron excesses in supernovae (Thielemann et al. 1990). Only nickel is significantly produced by SN Ia (Tsujimoto et al. 1995). Sodium is manufactured in massive stars by helium burning and expelled by SN II. So, we expect the ratios $[\text{Ni}/\text{Fe}]$ and $[\text{Na}/\text{Fe}]$ to show some correlation, at least in the early stages of chemical evolution. When SN Ia increase the nickel production, the correlation is affected, at the same point when the $[\alpha/\text{Fe}]$ and $[\text{Na}/\text{Fe}]$ ratios start to decline. So, the combination of sodium and nickel has been used to compare different contributions from SN Ia and SN II in halo stars (Nissen & Schuster 1997, 2010). They found a clear relation between $[\text{Na}/\text{Fe}]$ and $[\text{Ni}/\text{Fe}]$ in α -deficient stars with high Galactocentric distances. They argued that the outer halo is mostly composed by accreted dSphs and the Ni–Na relation is a merger indicator. However, further studies by Venn et al. (2004) pointed out this relation is less clear in accreted dwarf galaxies than in halo stars. They suggested the relation is naturally produced in massive stars. In addition, at lower metallicities, the behaviour of Na in dSphs is halo-like, but not at higher metallicities ($[\text{Fe}/\text{H}] > -1$) (Tolstoy et al. 2009).

In Fig. 12, we show the $[\text{Ni}/\text{Fe}]$ versus $[\text{Na}/\text{Fe}]$ relation for seven S2 members (red stars and triangles), together with other stars from dwarf galaxies. The original relation found by Nissen & Schuster (1997) for α -deficient halo stars is represented by a thick line. Fornax members (green circles) seem to roughly follow the Nissen–Schuster (N–S) relation. However, the S2 stars seem to behave in two different ways: i) The main-sequence/SGB population has decreasing $[\text{Ni}/\text{Fe}]$ at higher metallicities for almost the same $[\text{Na}/\text{Fe}]$ ratio, with the exception of CS29513–03 that shows a similar trend but with higher $[\text{Na}/\text{Fe}]$ ratio. This sodium enhancement is less likely to be attributed to mixing process in low giant branch phase (Gratton et al. 2000). ii) The evolved RGB population is clearly sodium-poor and fits nicely within the N–S relation. While in globular clusters, the O–Na anticorrelation is observed in the upper-RGB, there is no evidence of sodium enhancement in halo field stars (Gratton et al. 2000).

Since no further mixing episodes seem to be affecting S2 members, we suggest these two S2 groups (Na-rich and Na-poor) reflect the chemical signature of two different formation environments. One of them follows the N–S relation, whereas the other seems to behave quite different. This is consistent with the idea that the $[\text{Ni}/\text{Fe}]$ versus $[\text{Na}/\text{Fe}]$ relation is not an dSph indicator (Venn et al. 2004), and suggests that other mechanisms may well be playing a role.

archival low-resolution spectroscopy complemented by high S/N observations with HET/LRS2 to derive stellar parameters and carbon abundances consistently. Taking advantage of the stream’s proximity to the Sun, we have acquired high-resolution spectroscopic data for 7 Main Sequence S2 member stars with VLT/UVES, VLT/X-SHOOTER and GTC/HORuS and have measured the abundances of C, Li, Na, Al, Sc, α -elements (Mg, Si, Ca Ti), iron-peak elements (V, Cr, Mn, Fe, Co, Ni), and n-process elements (Sr, Ba). Finally, our high-resolution chemical abundances for high-surface gravity S2 members are combined with a revised and reduced sample of the likely S2 giant stars obtained by Roederer et al. (2010). We summarize the main results of our analysis below.

- Based on the combination of low- and high-resolution abundance measurements, we conclude that the metallicity distribution function (MDF) of the S2 member stars spans the range of $-2.7 < [\text{Fe}/\text{H}] < -1.5$. Additionally, there are two low-resolution spectroscopic S2 members with $[\text{Fe}/\text{H}] = -3$ and $[\text{Fe}/\text{H}] = -1.2$ respectively, possibly broadening the S2’s MDF even further. Based on the revised orbital properties, we conclude that the two most-metal poor stars from the original study of Roederer et al. (2010) with $[\text{Fe}/\text{H}] = -3.3$ and $[\text{Fe}/\text{H}] = -3.4$ cannot be assigned to S2 with confidence. Notwithstanding the uncertainty in the determination of the highest and the lowest levels of metal enrichment reached by the S2 stars, its MDF spans more than 1 dex in $[\text{Fe}/\text{H}]$ and therefore we conclude that without a shred of doubt the stream’s progenitor was a now defunct dwarf galaxy.

- The average of the three α -elements shows hints of a pattern consistent with a “knee” at $[\text{Fe}/\text{H}] < -2$, whose presence can not be established unambiguously. We note, however, that the individual tracks of Mg, Si, Ca and Ti as a function of $[\text{Fe}/\text{H}]$ appear rather flat, yet the existence of a gentle downward slope with increasing metallicity can not be ruled out. Importantly, throughout the entire $[\text{Fe}/\text{H}]$ range probed by the S2 members, the $[\text{Ti}/\text{Fe}]$ ratio stays firmly above that measured for the stars in the Sculptor dwarf satellite. In light of the behaviour of the S2 α abundances, we hypothesise that the progenitor galaxy was barely affected by the SN Ia pollution. S2’s star formation proceeded slowly and was cut short by its accretion and disruption by the Milky Way.

- The behaviour of the neutron-capture elements in S2 is remarkable. On one hand, the $[\text{Ba}/\text{Fe}]$ ratio is at the level consistent with the bulk of the halo stars and that of the classical dwarfs, like Sculptor and the globular clusters. This can be contrasted with the Ba ratios for the Galactic ultra-faint dwarfs, for which all but one (Reticulum 2) show an under-abundance of Ba compared to the field. On the other hand, many S2 stars with $[\text{Fe}/\text{H}] < -2$ show depleted levels of Sr, clearly below the halo trend at these metallicities and fully consistent with the behaviour of most of the Milky Way’s UFDs. Finally, the ratios of Sr and Ba (especially at $[\text{Fe}/\text{H}] < -2$) show an increased scatter compared to both the halo and dwarfs like Sculptor, indicative of the stochasticity of the enrichment process. The Sr/Ba pattern exhibited by the S2 stream is unique amongst the studied Galactic sub-systems and points to the existence of multiple (additional) sites of the production of neutron-capture elements.

- Our study provides new insights into the problem of

the Na-Ni relation with 3 measurements that do not seem to agree with the previously established Nissen-Schuster relation for slightly more metal-rich halo population.

- Finally, we also find S2 members are displayed in different regions of the $A(\text{C}) - [\text{Fe}/\text{H}]$ diagram with a significant fraction, $\sim 10\%$, located in the ancient CEMP-no group. This old population, rarely observed in other dwarf galaxies, supports the conclusion S2 is the shreds of a very unevolved progenitor system.

Taken together, the enrichment patterns of the elements available as part of our study of the S2 stream members point to a progenitor galaxy which is unlike any other dwarf satellite on orbit around the Milky Way. Star-formation in the S2 dwarf appears to have reached significant metallicity levels of $[\text{Fe}/\text{H}] \sim -1.5$ or perhaps even $[\text{Fe}/\text{H}] \sim -1.2$, yet with little evidence for SN Ia contribution. This primitive enrichment pattern is at odds with the absence of extremely metal poor stars in S2 and could instead indicate possible pollution from the nearby large galaxy, e.g. Milky Way. S2’s progenitor passes many chemical tests for a building block of the Galactic stellar halo, but fails spectacularly at the last hurdle - the neutron-capture element ratio. Our study provides a unique and previously unexplored view of star-formation and chemical enrichment at the high redshift, but it still leaves some puzzling questions unanswered.

7 DATA AVAILABILITY

All the data reduced and analyzed for the present article is fully available under request to the corresponding author⁹. Also, the UVES and X-SHOOTER data used in this article can be found in the original ESO archive¹⁰.

ACKNOWLEDGEMENTS

We thank Vanessa Hill for very useful comments about the nature of Sculptor galaxy. We also thank Chris Tout for highly appreciated suggestions. This work is partly based on data from the GTC Public Archive at CAB (INTA-CSIC), developed in the framework of the Spanish Virtual Observatory project supported by the Spanish MINECO through grants AYA 2011-24052 and AYA 2014-55216. The system is maintained by the Data Archive Unit of the CAB (INTA-CSIC). We would like to thank GRANTECAN staff members for their efficiency during the observing runs and all the effort done during HORuS commissioning. The Low Resolution Spectrograph 2 (LRS2) was developed and funded by the University of Texas at Austin McDonald Observatory and Department of Astronomy and by Pennsylvania State University. We thank the Leibniz-Institut f  r Astrophysik Potsdam (AIP) and the Institut f  r Astrophysik G  ttingen (IAG) for their contributions to the construction of the integral field units. Some of the figures within this paper were produced using IDL colour-blind-friendly colour tables (see Wright 2017). DA thanks the Leverhulme Trust for financial support. SK is partially supported by NSF grants

APPENDIX A: LITHIUM: A FOSSIL RECORD FROM EARLY UNIVERSE

Primordial lithium from Big Bang Nucleosynthesis (BBN) could be in principle measured in the atmospheres of unevolved metal-poor stars. Spite & Spite (1982b) and Rebolo et al. (1988) noticed an almost constant value for lithium abundance from the analysis of tens of VMP stars, $A(\text{Li}) = 2.2 \pm 0.1$. This value is named Lithium plateau or Spite plateau. Since then the regime on which the plateau has been observed has been expanded down to a metallicity $[\text{Fe}/\text{H}] < -6.1$ (Aguado et al. 2019a). High resolution observations have been also detected the plateau in ω Centauri (Monaco et al. 2010), the globular cluster M54 (Mucciarelli et al. 2014) and Sculptor dwarf galaxy (Hill et al. 2019). More recently, Molaro et al. (2020) also found the signature of the Lithium plateau in the major merger event in the *Gaia*-Sausage (Belokurov et al. 2018; Myeong et al. 2018d). That fact suggests whatever thing is responsible for the existence of the plateau is also happening outside of the Milky Way. Intriguingly, thanks to cosmological analysis of the Cosmic Microwave Background (CMB) the primordial lithium is calculated to be 2-3 times larger than observed in old stars (Spergel et al. 2003; Coc et al. 2013). This discrepancy is known as the cosmological lithium problem and is a longstanding problem in modern cosmology (see e.g., Fields 2011; Fields et al. 2020, and references therein).

We are able to measure the lithium double at 6707.8\AA in three S2 members, J0026+0037, J0049+1533, and J0206+0435. The values we derive are fully compatible with the plateau, $A(\text{Li}) = 2.3 \pm 0.1$, 2.20 ± 0.1 , and 2.26 ± 0.1 respectively, exacerbating the lithium problem. The level of lithium measured in these stars is another indicator of the slow chemical evolution suffered by S2. In Figure A1 we show the lithium measurements for unevolved metal-poor stars in S2 (red symbols), ω Centauri (Monaco et al. 2010) (green circles), the globular cluster M54 (Mucciarelli et al. 2014) (dark blue circle), the Sculptor galaxy (Hill et al. 2019) (light blue circle), the Slygr stream (Roederer & Gnedin 2019) (purple circles) and more Milky Way main-sequence turn-off halo stars from literature (grey circles). For completeness we add uncoloured triangles that represent more evolved S2 stars. As expected we clearly see how after dredge-up and mixing processes lithium is diluted (Brown et al. 1989; Gratton et al. 2000). Fig. A1 clearly suggest the lithium behaviour we find in canonical MW halo stars is the same than accreted satellites and extragalactic structures such as ω Centauri. We argue that the lithium abundance of the oldest stars is not affected by the environment they were formed and suggest the cosmological lithium

Figure A1. Lithium abundance, $A(\text{Li})$, versus metallicity, $[\text{Fe}/\text{H}]$, of the S2 stars observed with UVES (red stars) and MIKE (red triangles) compared with the values from ω Centauri (Monaco et al. 2010), the globular cluster M54 (Mucciarelli et al. 2014), the Sculptor galaxy (Hill et al. 2019), the Slygr stream (Roederer & Gnedin 2019), and other dwarf - turn-off stars ($\log g \geq 3.7$) with Li abundance values from Asplund et al. (2006); Frebel et al. (2008); Aoki et al. (2009b); Meléndez et al. (2010); Sbordone et al. (2010); Caffau et al. (2011); Sbordone et al. (2012); Masseron et al. (2012); Bonifacio et al. (2012); Hansen et al. (2014, 2015); Matsuno et al. (2017); Bonifacio et al. (2018); Aguado et al. (2019b) and references therein. We also include evolved S2 members from Roederer et al. (2010) (uncolored triangles) in which lithium is already depleted. The Lithium plateau (also called “Spite Plateau”) reference is shown as solid line at a level of $A(\text{Li}) = 2.20$ dex. Blue dashed line represents the primordial lithium value ($A(\text{Li}) \sim 2.7$) from WMAP (Spergel et al. 2003; Coc et al. 2013)

problem cannot be exclusively explained by near cosmology effects.

APPENDIX B: TABLES

This paper has been typeset from a \LaTeX file prepared by the author.

Table B1. Coordinates and stellar parameters from low-resolution analysis.

1: Objects with high-resolution analysis.

2: Objects with positive v_z motion

3: Objects with tentative [Fe/H] and [C/Fe] from low-resolution analysis

4: Objects with tentative [C/Fe] from low-resolution analysis

Table B2. APOGEE abundances for S2 members from ASPCAP.

APOGEE name	T _{eff}	log <i>g</i>	[Fe/H]	[C/Fe]	[Mg/Fe]	[Al/Fe]	[Si/Fe]	[Ca/Fe]	[Mn/Fe]	[Ni/Fe]	FLAG
